The distribution and kinetics of pamidronate was analysed using a two-compartment open model in rats. Solutions of [3H]-labelled pamidronate (0.5 mg/kg) were administered intravenously. Following equilibration, the perfusion rate was reduced to the steady state. The total uptake over 15 min was high (0.26 mg/kg). The total clearance rate was high (2.54 l/kg per h) and the total extraction ratio was low (0.29). During the initial 3 min of perfusion, the total distribution volume was 73 l (expressed as a volume of distribution in the peripheral compartment). A plasma-independent distribution, resulting from an equilibrium at the capillary or tissue level between the distribution sites and the plasma, was suggested by the fact that the value of the distributional clearance was the same as that of the total clearance. The pharmacokinetics were also studied after infusion of [14C]-labelled pamidronate (10 micrograms/kg per min
